We report nonresonant inelastic x-ray scattering from the semicore 5f levels of several actinide compounds. Dipole-forbidden, high-multipole features form a rich bound-state spectrum dependent on valence electron configuration and spin-orbit and Coulomb interactions. Cross-material comparisons, together with the anomalously high Coulomb screening required for agreement between atomic-multiplet theory and experiment, demonstrate sensitivity to the neighboring electronic environment, such as is needed to address longstanding questions of electronic localization and bonding in 5f compounds.

The valence electronic structure of actinide (5f) compounds exhibits a profound competition between localizing and delocalizing influences. On-site Coulomb, exchange, and spin-orbit interactions result in Hund’s rules and atomic-multiplet structure, but these are matched by nontrivial crystal fields and interatomic hybridization, enabling more band-like behavior. This interplay results in strongly correlated electronic behavior and complex phase diagrams for the light actinides while also fueling considerable theoretical challenges in the field. Consequently, while the understanding of actinide materials has grown appreciably in the last two decades, a fundamental grasp of their physical properties remains elusive.

From the perspective of application, difficulties in both theory and experiment are clear. First, the ab initio design of actinide-lanthanide separation agents is key to achieving sustainable nuclear power with decreased environmental impact. Recent studies of actinide chemical bonding are leading to a revision of previous notions of valence state and electronic orbital mixing, thus putting a premium on experimental methods sensitive to the valence electronic structure and low-energy electronic excited states. Second, the highest demand is on experimental methods which are both sensitive to the local electronic environment and also compatible with model environments mimicking the extreme conditions present in reactor vessels or fuel pre- or post-processing.

Core-level spectroscopies, such as x-ray-absorption spectroscopy (XAS) and electron energy-loss spectroscopy (EELS), have led to successful descriptions of the electronic ground states of transition-metal and rare-earth materials. For actinides, on the other hand, the situation is complicated by the short core-hole lifetime of tightly bound initial states, the constraints imposed by the dipole selection rule, and the practical difficulties imposed by the extreme surface sensitivity of XAS for low-energy edges.

Nonresonant inelastic x-ray scattering (NIXS) satisfies the driving motivations, above, for a new experimental technique for actinide science. For low-energy edges, NIXS uses hard x rays, so it is bulk-sensitive and compatible with extreme sample environments. Furthermore, NIXS is a flexible probe of local electronic structure: its selection rules can be tuned by variation of the momentum transfer of the scattering event. The NIXS signal is proportional to the dynamic structure factor

\[ S(q, \omega) = |\langle f | \hat{w}^{(f)} | i \rangle|^2 2 \delta(\Omega - \omega) \]

where \( q \) is momentum transfer, \( |i\rangle \) and \( |f\rangle \) are the initial and final electronic states in the target, \( \omega \) is photon energy loss, \( \Omega \) is the energy gain of the electronic state, and there are implicit sums over individual electronic coordinates, \( \mathbf{r} \), and final states, \( |f\rangle \). At low-momentum transfer, NIXS is a bulk-sensitive alternative to XAS, i.e., both are sensitive to dipole transitions. At increasing \( q \), high-order angular matrix elements begin to dominate Eq. (1) and NIXS probes final states inaccessible to dipole spectroscopy, including states of high final angular momentum. In either case, the final states probed are multielectronic, correlated excitations. Here, we show that NIXS provides a more direct and complete characterization of the \( \text{O}_{4.5} (5d\rightarrow5f) \) transition region, giving information germane to the central questions of localization, valence, and excited-state electronic structure in actinide compounds.

NIXS measurements were made using the lower-energy resolution inelastic x-ray scattering spectrometer at the PNC/XOR 20-ID beamline of the Advanced Photon Source. Experimental methods and data reduction follow previous methods; in particular, incident photon energy was \( \sim 10 \) keV and hence measurements were purely bulk-sensitive. NIXS energy resolution was around 1.3 eV (full width at half maximum, FWHM) and spectra were acquired at a rate of \( \sim 200 \) s/point. All samples were polycrystalline and data were taken in reflection geometry. EELS experiments on the \( \text{O}_{4.5} \) edge were performed as previously described. The preparation and handling of compounds were carried out with variations on the previous reports and
The clearest evidence supporting this conclusion is the strong agreement between the atomic-based theory and experiment, especially at higher \( q \). However, this accord requires unexpectedly high screening of the atomic Coulomb interaction. Coulomb matrix elements were set to only 60% of their atomic Hartree-Fock value, as opposed to the usual 80% for transition-metal and rare-earth systems. This suggests a broader range of theoretical approaches may be valuable in interpreting these spectra. In the atomic picture, one possible cause for the exaggerated screening is atomic configuration mixing, as investigated by Sen Gupta et al.\(^{16}\)
We can use the atomic picture to explain the general structure in the various high-$q$ NIXS spectra. By varying the strength of the spin-orbit coupling and the Coulomb interaction in the Th$^{4+}$ multiplet calculation, we find that the large scale, two-feature structure ($\approx 87$ and 94 eV for ThO$_{2+}$, $\sim 97$ and 104 eV for Cs$_2$UO$_2$Cl$_4$) of the NIXS spectra reflects $5d$ spin-orbit splitting, while the smaller splitting within each feature depends on the $5d$-$5f$ Coulomb interaction. Furthermore, the size of this measured spin-orbit gap is consistent with $5d$ electron binding energies measured by x-ray photoemission spectroscopy (XPS) for these systems. This is remarkable because in dipole-limit spectroscopies, the $5d$ spin-orbit splitting is invisible at the O$_{4,5}$ edge due to the high intrinsic broadening of the GDR.

A closer look at the spectra is required to identify the embedded atomic information. In particular, the Th$^{4+}$ calculation [Fig. 2(b)] predicts a mid-$q$ ($l=3$) resonance followed by the rise of a slightly lower energy feature at highest $q$ ($l=5$). This is observed quantitatively in both the low ($\sim 87$ eV) and high ($\sim 94$ eV) energy features in the ThO$_2$ spectra. However, it is also observed, qualitatively, in both the features that comprise the Cs$_2$UO$_2$Cl$_4$ spectrum even with the material’s higher oxidation state, differing metal-ligand coordination, and more covalent bonding. For ThO$_2$, there is a smaller separation between the $l=3$ and $l=5$ transition intensities for the high-energy feature. This difference in spacing makes the high-energy feature appear to “move” with $q$. The high-energy feature in the Cs$_2$UO$_2$Cl$_4$ is more widely split, so two distinct peaks are visible at moderate $q$, giving way to a well-defined shoulder as $q$ increases.

These arguments are strengthened by examining systems with nonzero $5f$ occupancy. In Fig. 3, we present measurements and calculations for UO$_2$ (homogeneously $5f^0$) and U$_3$O$_7$ (mixed-valent). Prethreshold excitations emerge in these spectra (at $\sim 97$ and 105 eV) in a generally similar fashion to the $5f^0$ case. However, in contrast to the $5f^0$ case, the $5f^2$ predictions put the $l=3$ and $l=5$ multipole transition intensities at the same energy for the higher-energy feature ($\sim 104$ eV), meaning that the NIXS high-energy peak position should be stable in energy with changes in $q$. This prediction is observed, meaning that feature location and motion as a function of $q$ fingerprint atomic-level properties of the system.

We now turn to the relationship between local chemistry and the NIXS $5d\rightarrow 5f$ spectra. As with the $5f^0$ materials, anomalously high Coulomb screening (50%) is required for best agreement in the $5f^2$ compounds, suggesting that this is a generic issue for light actinide materials. Such deviations from the isolated-atomic picture require a significant influence of the local electronic environment. Furthermore, the prethreshold region for U$_3$O$_7$ differs from that of UO$_2$ by a shift ($\sim 0.5$ eV higher) and broadening of the higher-energy feature. First, given the $+2/3$ change in idealized U oxidation state, this reflects metal $f$-electron structure that is not grossly perturbed by the extra oxygen inclusions. This supports actinide covalent bonds being more strongly $6d$ than $5f$ in character, a topic of continuing debate since the 1950s. Second, the modest spectral changes that are observed are reminiscent of a recent NIXS study where $4d$ core to valence excitations in $4f$ compounds demonstrated sensitivity to local environment and bonding characteristics. The direct interrogation of $5f$ states is a key advantage of studying the $4d_{5,5}$ higher-multipole transitions and suggests several future directions: pressure-dependent NIXS $O_{4,5}$ studies of heavier actinides (Am or Cm) would be a valuable probe of the Mott transition, while solution-phase studies would give important insight into the fundamental chemistry of the actinide-lanthanide separations process.

In summary, we report measurements and calculations for NIXS from $5d$ semicore states to $5f$ valence states. We find that high-order multipole transitions access states localized in nature and high in orbital angular momentum. Agreement with theory is good, subject to one subtle, but important caveat: the necessary use of unexpectedly large screening effects. This indicates an obvious direction for future theo-
tical work, in that one must include the effects of local environment in a fundamental way.\textsuperscript{16} Our results, together with the inherent compatibility of NIXS with extreme environments, strongly endorse the use of NIXS 5\textit{d}→5\textit{f} measurements in ongoing debates about the local electronic structure of actinide materials.
